## Abstract

The risk of neoplasm is elevated in patients with various autoimmune diseases. Although the overall risk of cancer in systemic lupus erythematosus (SLE) patients is slightly elevated, the standardized incidence ratio of several cancers is above 3.0. The main risk factor for neoplasm in this group is dysfunction of the immune system caused by the disease and by immunosuppressive drugs. The most common cancers in patients with SLE are related to viral latent infections caused by human herpesvirus 8, Epstein-Barr virus, and human papillomavirus. The risk of sarcoma has not been established in large cohort studies, but several case reports have been published. It remains uncertain whether there is a direct relationship between sarcoma and SLE.

We performed a systematic review of case reports and case series and analyzed the detailed data of 26 SLE patients with sarcoma. The most common sarcomas were Kaposi's sarcoma and leiomyosarcoma – 2 neoplasms that are potentially related to viral infection.

**Key words:** immunosuppressive therapy, viral infection, autoimmune disease, neoplasm, Kaposi's sarcoma.

## Introduction

An increased risk of neoplasms in patients with autoimmune diseases has been reported in the medical literature since the 1950s. To date, numerous cohort studies have shown that the overall risk of cancers, mainly hematological ones, is elevated in this group [1]. The risk for cancers in systemic lupus erythematosus (SLE) patients is slightly elevated, with the standardized incidence ratio (SIR) estimated to be between 1.2 and 2.6, although in most studies SIR was below 2.0 [2, 3]. For comparison, after kidney transplantation in graft recipients with or without SLE, SIR was estimated to be about 3.5 [4].

Two main risk factors for neoplasm in SLE have been proposed: immune system dysregulation caused by autoimmune disease, and immunosuppressive therapy [3, 5, 6]. Immune system dysfunction can explain the appearance

of neoplasms in the early phase of the disease, when immunosuppressive therapy had yet not been initiated or when the duration of this treatment was short and the cumulative dose of immunosuppressant drugs was relatively low. One disturbing aspect of these cases is the risk of misdiagnosis. In fact, there are several papers describing patients with cancer in whom SLE was a misdiagnosis, or when symptoms of lupus were eventually classified as paraneoplastic syndrome [7, 8].

It has been suggested that the dysfunction of both the cellular and humoral immune systems can promote oncogenesis in SLE [3, 5, 6, 9]. However, it seems that immunosuppressive treatment is a much stronger risk factor. Drugs used in SLE treatment are well known for their oncogenic potential. For example, cyclophosphamide is responsible for the increased risk of hematological and bladder cancers, and azathioprine for

non-Hodgkin lymphoma (NHL) and skin cancers [9, 10]. There is evidence of an increased risk of skin and bladder cancers after cyclophosphamide treatment in SLE patients [1, 10].

The overall risk for cancer in SLE is only slightly elevated. However, the risk of some neoplasms is much higher. In several studies, the SIR for NHL was established to be 3.5–5.5 [2, 11]. With the overall risk being slightly above 1.0 and some cancers being far more common, it is not surprising that some cancers in SLE had an SIR below 1.0.

Indeed, apart from neoplasms with SIR above 1.00 – hematological, lung, vulva, liver and thyroid cancers – there are malignancies with an incidence lower than in the general population, such as breast, endothelium, and prostate cancers [3, 11].

The risk of sarcoma in SLE is not well established. In two studies, the risk of sarcoma in SLE was high, with SIR reaching 49 and 12.1 [3, 12]. However, in these studies, the same group of 205 SLE patients (182 women and 23 men) was observed for 25 years (from 1967 to 2013) and only two cases of sarcoma were found. The authors concluded that the high SIR of sarcoma might be only “a chance finding” related to a relatively small group of subjects [3, 12].

In contrast, in several large, comprehensive studies published by Sasha Bernatsky’s group [2], the authors did not describe any case of sarcoma [2, 11, 13]. However, some evidence suggesting the possibility of sarcoma can be found in the literature. In one paper published in 2005 [2], in table 4, there is no information of sarcoma, despite the authors writing the following in the footnotes: “in addition to the categories present, the total include the following cancers: 21 non-melanoma skin [...], 5 connective tissue” [2]. In a recent paper, Bernatsky et al. [1] described a group of 1,668 SLE patients with 65 cancers, which included one case of sarcoma, although no details were provided. While the SIR of sarcoma was not calculated, one case of sarcoma among 65 cancers represents a relatively high frequency.

There is no information about sarcoma in some other studies [14, 15] published from 1974 to 2013. However, scant information can be found in the discussion section of the paper by Parikh-Patel et al. [14], who noted the increased risk of bladder cancer in SLE patients and cited a paper describing leiomyosarcoma of the bladder. The 5 cohort studies or case series presenting information on sarcoma in SLE patients are listed in Table I [1, 3, 4, 12, 16].

The risk of sarcoma in SLE is not well established, the main reason being its rarity and the variability of

connective tissue malignancies. However, several risk factors, mainly immunosuppressive treatment, support the hypothesis that the risk of sarcoma is elevated in SLE. The medical literature features several case reports. The aim of this study was to perform a systematic review of publications describing cases of sarcoma in SLE patients.

## Material and methods

To assess the risk of sarcoma in SLE patients, a systematic review on this topic was performed. The authors searched PubMed using the following terms: “(lupus or SLE or ‘lupus nephritis’) and (sarcoma or osteosarcoma or chondrosarcoma or Ewing or Kaposi or hemangioendothelioma or angiosarcoma or fibrosarcoma or myofibrosarcoma or chordoma or adamantinoma or liposarcoma or leiomyosarcoma or ‘malignant peripheral nerve sheath tumor’ or rhabdomyosarcoma or ‘malignant solitary fibrous tumor’ or dermatofibrosarcoma or ‘gastrointestinal stromal tumor’ or GIST)”.

A final search was conducted in March 2025, with the aim of including recent publications. A total of 378 titles of articles published between 1947 and 2025 were found. The articles were screened first through the title and abstract; 313 records were removed before screening. We identified 65 papers for further analysis, after which 8 cases of “lupus vulgaris” were identified and excluded from the analysis, in addition to 5 with hematological malignancies, 10 with benign tumors, and 6 cases with a misdiagnosis of SLE. In 5 case reports of SLE patients, sarcoma was not confirmed, and in 5 cases of sarcoma, SLE was not confirmed; these cases were also excluded. Of the remaining 26 papers, 4 were cohort studies and one was a review (Fig. 1). Only case reports were included in the analysis.

In total, 21 case reports described sarcoma in SLE patients. Fifteen full papers in English were obtained for analysis [10, 17–30]. Two additional papers were added after an analysis of the references [16, 31], and 1 was our work published in 2025 [32] (Table II).

Altogether, 20 patients were described in 18 full papers written in English. We also analyzed 6 cases described in abstracts [33–38], when the full paper was not written in English or when the full paper was not found but basic information could be obtained from the abstract (Table III).

## Results

Twenty cases described in detail in 18 full papers were analyzed [10, 16–32]. Information covering an ad-

**Table 1.** Cohort and review studies with information about sarcoma in SLE patients

Paper	Analyzed population	SLE patients with sarcoma	Results	Conclusions
Pettersson et al., 1992 Elevated risk of cancer in patients with systemic lupus erythematosus [3]	205 patients (182 women and 23 men) with SLE treated at the Helsinki University Central Hospital from 1967 to 1987	Two females (69 and 35 years old at the time of sarcoma diagnosis) with soft tissue sarcomas of lower limbs	15 cancers were diagnosed against 5.7 expected (RR 2.6) There were 2 soft tissue sarcomas against 0.04 expected (RR 49)	The same group was described in 2 papers. Tallbacka et al. wrote: "The patients in our study had a statistically significant elevated risk of soft-tissue sarcoma, based on 2 observed cases. This may be a chance finding"
Tallbacka et al., 2018 Elevated incidence of cancer in systemic lupus erythematosus: a Finnish cohort study with more than 25 years of follow-up [12]	The same group of 205 SLE patient cohort was followed for cancer incidence from 1967 to 2013		45 cancers were diagnosed. An elevated risk of overall malignancy (SIR 1.90) and an elevated risk of soft-tissue sarcoma (SIR 12.1) were reported	
Louthrenoo et al., 2003 Kaposi's sarcoma in rheumatic diseases [16]	Case report and cases from a Medline search, published between 1966 and 2002	Three cases of Kaposi's sarcoma in SLE patients	25 cases of Kaposi's sarcoma reported in rheumatic diseases (11 men and 14 women)	8 patients with rheumatoid arthritis, 5 with polymyositis/dermatomyositis, 5 with vasculitis, 3 with SLE, 2 with polymyalgia rheumatic, 1 with undifferentiated connective tissue disease and 1 with Behçet disease
Ramsey-Goldman et al., 2016 Standardized incidence ratios (SIRs) for cancer after renal transplant in systemic lupus erythematosus (SLE) and non-SLE recipients [4]	143,652 renal transplant recipients with and without SLE contributed 585,420 patient years of follow-up to determine incident cancers using Medicare claim codes. From 2001 to 2009	The risk of Kaposi's was elevated in both groups	10 160 cancers occurred at least 3 months after renal transplant. Overall cancer risk was increased in both SLE (SIR 3.5) and non-SLE (SIR 3.7) groups compared with the US general population	Cancer risk in renal transplant recipients was similar in SLE and non-SLE subjects, aside from melanoma. The risk of melanoma was higher in the SLE group
Bernatsky et al., 2021 Cancer risk in a large inception SLE cohort: Effects of demographics, smoking, and medications [1]	1668 patients meeting ACR criteria for SLE across 33 centers (from 1999 to 2011) with an average 9 years of follow-up	One case of sarcoma	65 cancers occurred: 15 breast, 10 non-melanoma skin, 7 lung, 6 hematological, 6 prostate, 5 melanoma, 3 cervical, 3 renal, 2 each gastric, head and neck, and thyroid, and 1 each rectal, sarcoma, thymoma, and uterine cancers	No details of a single case of sarcoma were described

ACR – American College of Rheumatology, RR – relative risk, SLE – systemic lupus erythematosus; SIR – standardized incidence ratio.

**Fig. 1.** Flow chart illustrating the procedure for article inclusion and exclusion in the systematic review of sarcoma in SLE patients.

ditional 6 cases was found only in abstracts (full papers were not written in English or were not available) [33–38]. The information from abstracts was scarce, although the essential data about age, sex of patients, and the type of sarcoma and its location were found.

All patients except 1 [18] were females, originating from different countries and continents. There was no precise information about racial and ethnic predominance. The mean age of all 26 patients at the time of sarcoma diagnosis was  $39.35 \pm 13.2$  years; the youngest patient was 18 [21], and the oldest 78 years of age [36].

The most common diagnosis was Kaposi's sarcoma, representing 30.8% (8/26) of all sarcomas [16, 17, 20, 28, 31, 36, 38], followed by 7 leiomyosarcomas (26.9% of all sarcomas) [10, 22, 24, 29, 35, 37]. The remaining 11 sarcomas were represented by single cases, showing the huge variety of connective tissue neoplasms.

The skin was the organ most frequently involved, and 7 patients had Kaposi's sarcoma of the skin. In 4 patients, sarcoma was located in the bladder, and at least 3 of these patients had been treated with cyclophosphamide before the sarcoma diagnosis [10, 25]. In 1 case,

there was no information about immunosuppression. Three sarcomas were located in bones (calcaneum, tibia and femur), 3 in the breast, 2 in the mucosa, 2 in the retroperitoneal space, and 2 in the left atrium. Moreover, there were single cases of sarcoma of the abdominal wall, liver, and renal allograft. In 1 case, the disease was disseminated at the time of diagnosis.

In 18 cases, information regarding the duration of SLE before sarcoma was available, and this ranged from 3 months to 19 years (mean  $9.07 \pm 5.36$  years).

The immunosuppressive regimens varied substantially, reflecting the progress that was achieved in SLE treatment over a period of half a century. The early cases were treated with glucocorticosteroid, azathioprine, and cyclophosphamide; the last patients were receiving hydroxychloroquine, methotrexate, mycophenolate mofetil, and belimumab.

In 15 out of 19 cases, surgery was the main treatment. Radiotherapy was the only treatment in 1 case, and adjuvant in 5 others. Chemotherapy was used in 3 cases but never as the sole treatment. Glucocorticosteroid discontinuation or reduction was used in 2 Kaposi's sarcoma patients. This approach leads to a short-term improvement, but in the follow-up a relapse of SLE and recurrence of sarcoma were observed. There is information about 7 deaths in 21 cases (in 5 cases, the follow-up was not mentioned). The follow-up after sarcoma treatment ranged from 4 to 60 months; consequently, the real mortality is difficult to establish.

## Discussion

Sarcomas are heterogeneous malignancies of connective tissue. The systematics of sarcoma is difficult, with this field being generally divided into two groups: bone and soft tissue sarcomas. Primary bone sarcomas account for less than 0.2% of malignant neoplasms across all ages. The overall incidence rate ranges between 0.8 and 0.9 cases per 100,000/year. The most common bone sarcomas are osteosarcoma and Ewing sarcoma. Some neoplasms, such as giant cell tumors of bone, are only locally aggressive and rarely metastatic [39]. The incidence of soft tissue sarcomas in adults in Europe is approximately 4–5 cases per 100,000/year, with the average age of diagnosis being 59 years. The most common are leiomyosarcoma and liposarcoma [40].

Sarcomas represent 1% of all cancers. This rarity makes it difficult to calculate the risk in patients with SLE. Well-known risk factors for sarcomas are exposure to various chemicals and ionizing radiation [39, 40]. Patients with SLE are generally more exposed to both these factors, yet immunosuppressive drugs seem to be the most important risk factor.

Exposure to immunosuppression is a well-known risk factor for cancers [3, 5, 6]. All the patients described above received some immunosuppressive medication, although this was administered in different regimens with different durations and various doses. It is impossible to assess which treatment was the most harmful, if any. However, not only drugs but also the disease itself lead to immune system dysfunction. The impact of immune dysfunction on the risk for sarcoma could not be assessed on the basis of case reports. In our review, at least seven sarcomas were diagnosed in the first 5 years of SLE treatment [17, 20–22, 27, 31, 34]. However, the majority of cases were diagnosed in patients with a much longer history of immunosuppressive treatment.

In patients with neoplasms diagnosed shortly after the onset of SLE, the possibility of misdiagnosis should be taken into consideration. The literature features cases of angiosarcoma [8] and primary sarcoma of the heart [41] mimicking lupus. In 1 case presented in our review, Kaposi's sarcoma was diagnosed only 3 months after SLE onset. In this case, there was no doubt about SLE diagnosis, as the patient presented typical symptoms, laboratory abnormalities, and an immunological test, resulting in lupus nephritis being confirmed by kidney biopsy [17].

Interestingly, the first cases of sarcoma following lupus were published several years before azathioprine was synthesized in 1957. Unfortunately, only the titles of papers written by Kopf in 1947 [42] and Winkle in 1950 [43] were available for the authors of this review; therefore, no information of the treatment of these patients was found.

In 1904, many years before modern immunosuppressive therapy, Perthes described a case of a spindle cell sarcoma that followed radiation therapy for lupus, which was one of the first cases of a neoplasm after radiotherapy [44]. The harmful effect of ionizing radiation is a well-recognized risk factor for neoplasms. However, it was impossible to

provide even a rough estimate of the radiation dose in patients described in case reports, although it is clear that SLE patients underwent more imaging studies in their life than healthy ones.

One very interesting problem is the impact of viral infection. In this review, 30.8% of patients had Kaposi's sarcoma and 26.9% had leiomyosarcomas. Kaposi's is an extremely rare neoplasm, but is a typical cancer of immunocompromised patients, strongly related to viral infection caused by human herpesvirus 8 (HHV-8). In 2003, Louthrenoo et al. [16] described cases of Kaposi's sarcoma in rheumatoid diseases. Twenty-five cases were reported (11 men and 14 women); 8 patients had rheumatoid arthritis (RA), 5 had polymyositis/dermatomyositis, 5 had vasculitis, 3 had SLE, 2 had polymyalgia rheumatica, 1 patient had a case of undifferentiated connective tissue disease, and 1 had Behcet's disease.

Leiomyosarcoma, on the other hand, is one of the most common sarcomas. Therefore, it is not surprising that it was also the second most common in the present review. It is, however, important to note that this sarcoma could also be related to viral infection caused by the Epstein-Barr virus (EBV). Epstein-Barr virus is a life-long asymptomatic infection carried by the vast majority of individuals in all human populations. Epstein-Barr virus infection is associated with hematological (Hodgkin lymphoma, Burkitt lymphoma, diffuse large B cell lymphoma, plasmablastic lymphoma and primary effusion lymphoma) and solid (nasopharyngeal carcinoma, gastric carcinoma, leiomyosarcoma) malignancies [45]. In 2007, Chan et al. [22] precisely described a relationship between EBV infection and leiomyosarcoma in a patient with SLE, but this approach is uncommon, and in most cases of leiomyosarcoma there is no information about any viral infection.

The problem with virus-related neoplasm in immunocompromised patients is an interesting issue. In patients with SLE, there is a higher risk of hematological, lung, vulva, liver and thyroid cancers [3, 11], which is probably related to viral infections. Human papilloma-virus infection is related to vulva and cervical cancers, EBV to hematological and leiomyosarcoma, and HHV8 to Kaposi's sarcoma [46]. Dreyer et al. [15] described 61 malignancies in an SLE population and estimated that 29 (47.5%) were "potentially associated" with viral infection. However, no subject had sarcoma.

Latent viral infection in patients treated with immunosuppression seems to be the main risk factor of sarcoma in SLE.

The cancers with low SIR in SLE are not related to viral infection but are hormone-dependent: the risk of breast, endothelium, ovarium, and prostate cancers is relatively low in SLE [3, 11].

The role of an immune dysfunction in sarcoma development is difficult to estimate. It could, however, explain the occurrence of sarcoma in patients treated with various regimens for various periods of time. It is also not surprising that several cases of sarcoma have been described in patients with other connective tissue diseases, such as discoid lupus erythematosus [47], Sjögren's syndrome [32], antiphospholipid antibody syndrome [48] and RA [16].

## Conclusions

Patients with SLE have an elevated risk of cancer compared to the general population. The risk of sarcoma is difficult to calculate, because both conditions – SLE and sarcoma – are relatively rare. Thus far, no direct relationship between sarcoma and SLE has been established. The development of large databases of rheumatological diseases and their analysis based on artificial intelligence may in the future enable estimation of the risk of coexistence of these two rare diseases.

Indeed, immune system dysfunction caused by autoimmune disease and immunosuppressive drugs and exposure to ionizing radiation are risk factors for occurrence of sarcoma in the SLE population. The newer therapies are safer than those used several years ago, and the availability of imaging studies makes it easier to perform them in patients with chronic diseases such as SLE. Modern immunosuppression and limitation of imaging studies seem to be the best means of prophylaxis of sarcoma.

There is no good screening for sarcoma. The most common sarcoma in SLE is Kaposi's sarcoma of the skin. An examination of the patient's skin is essential. Also, it is important not to ignore any tumors and bumps reported by the patient.

Another interesting issue concerns the relationship between viral infection and sarcoma. In the future, new vaccines and new antiviral drugs will probably change the epidemiology of cancers in immunocompromised patients.
